Dynamic Slider with Fetched Data

Overview

This implementation extends the image slider component by integrating asynchronous data fetching and dynamically generating slider content from API responses. Instead of displaying static images, the slider now renders user information cards retrieved from an external API endpoint.

Building on Previous Concepts

This code combines two previously covered topics:

- **Image Slider:** The core slider functionality with navigation controls (next, previous, play/pause) and automatic transitions remains unchanged.
- **Fetch API:** The asynchronous data retrieval pattern using `async/await` syntax to request and parse JSON data from external sources.

The primary modification is replacing hardcoded image elements with dynamically created card elements populated with fetched user data.

Key Structural Changes

Modified Slider Container

The slider container now starts empty and receives its content programmatically:

```
<div class="slider-container">
    <!-- Content will be injected here dynamically -->
    <button id="btnNext" class="sliderbutton next">&#10095;</button>
    <button id="btnPrev" class="sliderbutton prev">&#10094;</button>
    <button id="btnPlay" class="sliderbutton play">&#x23f8;</button>
</div>
```

Card Styling

Additional CSS defines the visual presentation of user data cards:

```
.card {
    display: grid;
    height: 400px;
    gap: 16px;
    justify-content: center;
}
```

Output:

The `display: grid` property enables vertical alignment of card content, while `justify-content: center` horizontally centers the information within each card.

Data Fetching Implementation

Asynchronous Data Retrieval

The `fetchJSON()` function handles API communication:

```
async function fetchJSON() {
    const response = await fetch("https://jsonplaceholder.typicode.com/users");

    if (!response.ok) {
        throw new Error("Request failed");
    }
    return response.json();
}
```

Output:

Powered by SPRK Technologies

This function requests user data from the JSONPlaceholder API, validates the response status, and converts the response body to a JavaScript object array.

Data Loading with Error Handling

```
var users = [];

async function loadData() {
    try {
        users = await fetchJSON();
        console.log(users);
    }
    catch (err) {
        console.error(err);
    }
}
```

Output:

The `loadData()` function populates the `users` array with fetched data. Error handling ensures that network failures or API issues are logged without breaking the application.

Dynamic Card Generation

Creating Elements Programmatically

The initialization function generates slider cards from the fetched data:

```
async function init() {
    await loadData();

    users.forEach(user => {
        let card = document.createElement("div");
        card.classList.add("card");
        card.classList.add("sliderimage");
        card.innerHTML = `
```

Powered by SPRK Technologies

```
            <h2 class="name">${user.name}</h2>
            <div class="address">
                <ul>
                    <li>${user.address.suite}</li>
                    <li>${user.address.street}</li>
                    <li>${user.address.city}</li>
                    <li>${user.address.zipcode}</li>
                </ul>
            </div>
            <p>${user.email}</p>
        `;
        sliderContainer.insertAdjacentElement("afterbegin", card);
    });
}
```

Output:

Each user object is transformed into a card element. Template literals enable clean HTML structure definition with embedded user data. The `insertAdjacentElement("afterbegin", card)` method inserts each new card at the beginning of the container, resulting in reverse order insertion.

Understanding insertAdjacentElement

The `insertAdjacentElement()` method provides precise control over element insertion position:

```
sliderContainer.insertAdjacentElement("afterbegin", card);
```

Position options include:

- `"beforebegin"` : Before the element itself
- `"afterbegin"` : Inside the element, before its first child
- `"beforeend"` : Inside the element, after its last child
- `"afterend"` : After the element itself

Output:

Powered by SPRK Technologies

> Using `"afterbegin"` ensures each new card appears at the start of the container, pushing previous cards down. This creates a reverse chronological order when iterating through the array.

The cloneNode() Method

Understanding Node Cloning

The `cloneNode()` method creates a duplicate of a DOM node. It accepts a boolean parameter that determines the cloning depth:

```
const fixedClone = lastCard.cloneNode(true);
```

Parameters:

- `cloneNode(false)` or `cloneNode()` : Shallow clone — copies only the element itself, without child nodes
- `cloneNode(true)` : Deep clone — copies the element and all its descendants (child elements, text nodes, etc.)

Purpose in This Implementation

After generating all slider cards, a fixed placeholder is required to prevent layout collapse:

```
const cards = sliderContainer.querySelectorAll(".card");
const lastCard = cards[cards.length - 1];

const fixedClone = lastCard.cloneNode(true);
fixedClone.classList.add("fixed");
fixedClone.classList.remove("card");
fixedClone.classList.remove("sliderimage");

sliderContainer.appendChild(fixedClone);
```

> **Output:**

Powered by SPRK Technologies

Since all slider images are absolutely positioned (`position: absolute`), they are removed from the normal document flow. This causes the container to collapse to zero height. The fixed clone uses `position: static` (the default) to maintain the container's height while remaining invisible (`opacity: 0`).

Why Clone Instead of Create?

Cloning the last card ensures the fixed element has identical dimensions and structure to the actual slider content. Creating a new element would require manually replicating all styles and content, which is error-prone and less maintainable.

Alternative Approach

The class modifications can be simplified to a single line:

```
fixedClone.className = "fixed";
```

Output:

Setting `className` directly replaces all existing classes with the specified value, achieving the same result as the three separate operations.

Complete Initialization Flow

```
async function init() {
    await loadData();

    users.forEach(user => {
        let card = document.createElement("div");
        card.classList.add("card");
        card.classList.add("sliderimage");
        card.innerHTML = `
            <h2 class="name">${user.name}</h2>
            <div class="address">
```

Powered by SPRK Technologies

```
                <ul>
                    <li>${user.address.suite}</li>
                    <li>${user.address.street}</li>
                    <li>${user.address.city}</li>
                    <li>${user.address.zipcode}</li>
                </ul>
            </div>
            <p>${user.email}</p>
        `;
        sliderContainer.insertAdjacentElement("afterbegin", card);
    });

    sliderContainer.firstElementChild.classList.add("show");

    const cards = sliderContainer.querySelectorAll(".card");
    const lastCard = cards[cards.length - 1];

    const fixedClone = lastCard.cloneNode(true);
    fixedClone.classList.add("fixed");
    fixedClone.classList.remove("card");
    fixedClone.classList.remove("sliderimage");

    sliderContainer.appendChild(fixedClone);

    allImages = document.querySelectorAll(".sliderimage");
    sliderAnim = setInterval(nextSlide, 5000);
}

init();
```

Output:

The initialization sequence: (1) Fetch user data asynchronously, (2) Generate card elements for each user, (3) Mark the first card as visible, (4) Create and append the fixed placeholder, (5) Initialize slider variables, (6) Start automatic transitions.

Integration with Existing Slider Logic

The navigation and animation logic remains identical to the image slider implementation. The `nextSlide()` function and button event listeners work seamlessly with card elements because they rely on CSS classes (`.sliderimage` and `.show`) rather than element types.

```
function nextSlide() {
    currentSlide++;
    if (currentSlide >= allImages.length) {
        currentSlide = 0;
    }
    allImages.forEach(function(ele, idx) {
        ele.classList.remove("show");
        if (idx == currentSlide) {
            ele.classList.add("show");
        }
    });
}
```

Output:

This function operates on any element with the `sliderimage` class, whether it's an `<img>` element or a dynamically created `<div>` card.

Key Takeaways

- **Component Reusability:** Well-structured components can be adapted to different content types without modifying core functionality.
- **Separation of Concerns:** CSS class-based styling and behavior attachment enables content-agnostic implementations.
- **cloneNode() Applications:** Node cloning provides an efficient method for duplicating complex DOM structures with all attributes and child elements intact.
- **Asynchronous Initialization:** Async/await patterns facilitate sequential operations that depend on external data sources.

- **Dynamic Content Generation:** Template literals combined with array iteration methods enable scalable content rendering from data structures.

Practical Applications

This pattern applies to various scenarios requiring dynamic content presentation:

- Product carousels populated from e-commerce APIs
- Testimonial sliders with database-driven content
- Image galleries with metadata from content management systems
- News tickers displaying real-time updates from feeds
